

The Rise and Fall of Great Technologies and Powers

Jeffrey Ding⁺

Abstract

How do technological revolutions affect the rise and fall of great powers? Scholars have long observed that major technological breakthroughs disrupt economic power balances, yet they rarely investigate how this process occurs. Existing studies establish that a nation's success in adapting to revolutionary technologies is determined by the fit between its institutions and the demands of these technologies. The standard explanation emphasizes institutions suited for monopolizing innovation in new, fast-growing industries (leading sectors). I outline an alternative pathway based on general-purpose technologies (GPTs), foundational advances that boost productivity only after an extended diffusion process across many sectors. Specifically, GPT diffusion demands institutional adaptations that widen the base of engineering skills associated with a GPT. To test this argument, I set the GPT mechanism against the leading-sector mechanism across three cases, which correspond to past industrial revolutions: Britain's rise to preeminence in the early 19th century; the U.S.'s overtaking of Britain before World War I; Japan's challenge to U.S. technological dominance in the late 20th century. The findings support a novel explanation for technology-driven power transitions, directly bearing on how emerging technologies like AI, which some regard as driving a fourth industrial revolution, could influence a possible U.S.-China power transition.

I. Introduction

Policymakers and scholars increasingly frame today's U.S.-China rivalry as a contest for technological leadership in the "Fourth Industrial Revolution."¹ How do technological revolutions affect the rise and fall of great powers? International relations scholars have long recognized that major technological advances often precede economic power transitions, with implications for global military and political leadership. As Yale historian Paul Kennedy has established, the rise and fall of great powers involves "differentials in growth rates and technological change, leading to shifts in the global economic balances, which in turn gradually impinge upon the political and military balances."² Yet, while scholars have debated how shifts in economic balances affect military power and geopolitical influence, few studies scrutinize the very first step of Kennedy's causal chain: the link between technological change and differentials in long-term growth rates among great powers.³

Among those that do, the standard account stresses dominance over critical technological innovations in new, fast-growing industries (*leading sectors*). By exploiting a brief window to monopolize profits in cutting-edge industries, the country that dominates innovation in these sectors rises to become the world's most productive economy. The fit between domestic institutions and emerging technologies explains why the benefits of leading sectors tend to accrue in certain nations. Some scholars argue that national systems of political economy of rising challengers can more rapidly adapt to the demands of new, revolutionary technologies. Leading economies, by contrast, are victims of their past success, burdened by powerful vested interests that resist adaptation to disruptive technologies.⁴ Other scholars outline more specific institutional factors, such as the

¹ Doshi 2021.

³ Gilpin 1981; Kennedy 1987; Kirshner 1998.

⁴ Gilpin 1996; Moe 2009.

degree of government centralization or industrial governance structures, that account for why some countries monopolize leading sectors.⁵

I challenge the leading-sector (LS) interpretation of technology-driven power transitions on empirical and theoretical grounds. I develop an alternative explanation centered on general-purpose technologies (GPTs), fundamental advances that can spur economic transformation. Distinguished by their potential for continuous improvement, pervasive applicability throughout the economy, and synergies with complementary innovations,⁶ GPTs make a substantial impact on economic productivity only after a “gradual and protracted process of diffusion into widespread use.”⁷ Electricity, the prototypical GPT, followed this extended trajectory. The first electric dynamo practical for industrial use emerged in the 1870s, but its impact on overall productivity took five decades to materialize.⁸

GPTs, therefore, affect economic power transitions in a pathway that differs significantly from the standard LS account. Specifically, these competing interpretations of technology-driven power transitions differ along three key dimensions: impact timeframe, phase of relative advantage, and breadth of growth. First, whereas the LS explanation emphasizes the impact of technological innovations in the early stages of their life cycle, the greatest boosts to productivity come late in a GPT’s development. Second, the GPT explanation places more weight on diffusion. No one country dominates innovations in GPTs; rather, national success is determined by a state’s effectiveness in adopting GPTs across a wide range of economic sectors. Finally, in contrast to the LS account’s focus on a limited number of new industries’ contributions to economic growth, GPT-fueled productivity growth is spread across a broad range of industries.

⁵ Drezner 2001; Kitschelt 1991.

⁶ Bresnahan and Trajtenberg 1995.

⁷ David 1990.

⁸ Devine 1982.

Clearly differentiating between these two pathways informs the institutional factors most crucial to economic leadership amidst technological revolution. If the LS trajectory holds, then the key institutional adaptations allow states to seize the market in new industries, such as scientific research investments that pioneer new technological paradigms and industry structures that monopolize LS innovation. If, however, the GPT model is operative, the key institutional complementarities facilitate widespread diffusion of GPTs, including education systems and technical associations that broaden the base of engineering skills associated with a GPT.

I test this argument with three historical case studies that set the GPT mechanism against the LS mechanism: Britain's rise to preeminence in the first industrial revolution (1780-1840); the U.S.'s overtaking of Britain in the second industrial revolution (1870-1914); and Japan's challenge to America's technological dominance in the information technology revolution (1960-2000). The case studies cover periods characterized by both remarkable technological change — the “three great industrial revolutions” in the eyes of some scholars⁹ — and significant fluctuations in the global balance of economic power. Though all three cases favor the LS account in terms of both background conditions and prior theoretical discussions, the case study evidence reveals that GPT diffusion was central to how each technological revolution translated into differential rates of economic growth among the great powers.

By deepening our understanding of how technological revolutions cause power transitions, this article makes three primary contributions. First, it introduces and defends GPT diffusion theory as a novel explanation for how and when technological change can lead to a power transition. The evidence herein supports the explanatory power of GPT diffusion theory over the standard explanation of technology-driven power transitions based on leading sectors, which exerts enduring

⁹ von Tunzelmann 1997, 2.

influence in policy and academic circles.¹⁰ In doing so, this article answers the call for the international relations field to devote more attention to the causes of power transitions, not just their consequences.¹¹ Second, GPT diffusion theory revises accepted thinking about how emerging technologies could influence the existing U.S.-China balance. Existing work on this topic emphasize China's capacity to innovate in new leading sectors and capture monopoly rents from new discoveries.¹² This article highlights the importance of institutions that widen the pool of engineering skills linked to GPTs, which are often ignored by innovation-centered accounts of U.S.-China technological competition.

More broadly, this paper demonstrates an approach to unpack the causal effects of technological change on international politics. One obstacle to researching the technological drivers of changes in the international balance of power, which Harold Sprout articulated back in 1963, is that most theories either grossly underestimate the implications of technological advances or assume technological advance is the “master variable” of international politics.¹³ This article takes the middle ground. Technology does not determine the rise and fall of great powers, but some technological trends, like the diffusion of GPTs, do seem to gain an inertia of their own. Social and political factors, such as institutional adaptations to build GPT skill infrastructure, shape the pace and direction of these technological trends. This approach is particularly useful for understanding the effects of technological change across larger scales of time and space.

This article proceeds as follows. I first outline the theoretical differences between the GPT and LS mechanisms. I then assess the explanatory power of these two mechanisms by tracing how technological changes affected economic power transitions in history's three industrial revolutions,

finding in favor of GPT diffusion theory. The conclusion sets forth the broader implications of my findings.

II. Theories of Technological Change and Power Transition

Existing studies establish that a nation's success in adapting to revolutionary technologies is determined by the match between its institutions and the demands of these technologies. Such analyses tend to fixate on the most dramatic aspects of technological change — “eureka” moments and first implementations of radical inventions. Consequently, standard explanations of technology-driven power transitions focus on the suitability of a rising power's institutional arrangements for cornering profits in leading sectors.

GPT diffusion theory, by contrast, draws attention to the less spectacular process by which fundamental innovations gradually diffuse throughout many industries. The rate and scope of diffusion is particularly relevant for GPTs. Recognized by economists and historians as “engines of growth,” GPTs hold immense potential for boosting productivity.¹⁴ Realizing that promise, however, entails continuous changes across a wide range of technology systems. Under this pathway, the key institutional competencies are those that facilitate GPT diffusion. Specifically, this explanation highlights the significance of education and training systems that widen the pool of engineering skills and knowledge linked to new GPTs.

GPT DIFFUSION AND LS PRODUCT CYCLES

The dominant explanation for how technological change drives power transitions emphasizes a country's dominance in leading sectors, new industries that experience rapid growth on the back of new technologies. Cotton textiles, steel, chemicals, and the automobile industry form a “classic sequence” of “great leading sectors,” developed initially by economist Walt Rostow and

¹⁴ Bresnahan and Trajtenberg 1995.

adapted by political scientists.¹⁵ Maintaining a monopoly on innovation in these emerging industries, according to the LS account, determines the rise and fall of lead economies.

This model of technological change and power transition builds on the international product life cycle, a concept pioneered by Raymond Vernon. Constructed to explain patterns of international trade, the product cycle begins with product innovation and the growth of sales in the domestic market. Once the domestic market is saturated, the product is exported to foreign markets, which eventually results in the diffusion of the manufacturing of the product, thereby eliminating the innovator's monopoly profits.¹⁶ In fact, explicit references to the product cycle appear in many LS-based studies.¹⁷ One scholar described Gilpin's *U.S. Power and the Multinational Corporation*, an influential text for the LS mechanism, as "[having] drawn on the concept of the product cycle, expanded it into the concept of the growth and decline of entire national economies, and analyzed the relations between this economic cycle, national power, and international politics."¹⁸

The product cycle's assumptions illuminate the differences between the GPT and LS mechanisms along three key dimensions. In the first stage of the product cycle, a firm generates the initial product innovation and profits from sales in the domestic market before saturation. Extending this model to national economies, the LS mechanism emphasizes the clustering of LS innovations and attendant monopoly profits in a single nation.¹⁹ "The extent of national success that we have in mind is of the fairly extreme sort," write Modelski and Thompson. "One national economy literally dominates the leading sector during its phase of high growth and is the primary beneficiary of the immediate profits."²⁰ The GPT trajectory, in contrast, places more value on where

²⁰ Modelski and Thompson 1996, 91. See also Thompson 1990, 217.

technologies are diffused than where an innovation is first pioneered. I refer to this dimension as the *phase of relative advantage*.

In the next stage, the product innovation spreads to global markets and the technology gradually diffuses to foreign competitors. Monopoly profits associated with a product innovation dissipate, as production of the innovation becomes routinized and transfers fully to other countries. Mirroring this logic, Modelski and Thompson write, “[Leading sectors] bestow the benefits of monopoly profits on the pioneer until diffusion and imitation transform industries that were once considered radically innovative into fairly routine and widespread components of the world economy.”²¹ Thompson states, “the greatest marginal stimulation to growth may therefore come early in the sector’s development at the time when the sector itself is expanding rapidly.”²²

The GPT trajectory assumes a different *impact timeframe*. As noted earlier, because GPTs require major structural changes across countless industries, their greatest marginal stimulation to growth comes decades after their emergence.²³ It is precisely the period when diffusion transforms radical innovations into routine components of the economy — the stage which LS scholars say the causal effects of leading sectors dissipate — that generates the productivity gap between nations.

The product cycle also reveals differences between the LS and GPT mechanisms regarding the *breadth of growth*. Like the product cycle’s focus on an innovation’s life cycle within a singular industry, the LS mechanism emphasizes the contributions of a limited number of new industries to economic growth in a particular period. GPT-fueled productivity growth, on the other hand, is dispersed across a broad range of industries.²⁴ Table 1 specifies how LS product cycles differ from GPT diffusion along the three dimensions outlined above. Crucially, these technological trajectories

shape the institutional factors that are most important for national success in adapting to periods of technological revolution.

TABLE 1. *Two Mechanisms of Technological Change and Power Transitions*

<i>Mechanisms</i>	<i>Impact timeframe</i>	<i>Phase of relative advantage</i>	<i>Breadth of growth</i>	<i>Institutional complements</i>
LS Product Cycles	Lopsided in early stages	Monopoly on innovation	Concentrated	Deepen skill base in LS innovations
GPT Diffusion	Lopsided in later stages	Edge in diffusion	Dispersed	Widen skill base in spreading GPTs

INSTITUTIONS FOR GPT DIFFUSION: GPT SKILL INFRASTRUCTURE

New technologies agitate existing institutional patterns. They appeal for government support, generate new collective interests in the form of technical societies, and induce organizations that train people in relevant fields. If institutional environments fail to adapt, the development of new technologies is hindered. As Gilpin articulates, a nation’s technological “fitness” is rooted in the “extent of the congruence” between its institutions and the demands of evolving technologies.²⁵

If GPTs drive economic power transitions, which institutions fit best with their demands? Institutional adaptations for GPT diffusion must solve two problems. First, capturing the benefits of GPTs requires extensive coordination between the GPT sector and numerous application sectors. Without access to complementary assets embedded across many complex application scenarios, the sheer reach of a GPT places heavy demands on innovating firms in the GPT sector. Given the sheer scope of potential applications, it is infeasible for firms in the GPT sector to commercialize the technology on their own, as the necessary complementary assets are embedded with different firms and industries.²⁶ Thus, coordination between the GPT sector and other organizations that provide

²⁵ Gilpin 1996, 413. See also Perez 2002.

²⁶ Teece 2018. In the AI domain, as one example of a potential GPT, firms that develop general machine learning algorithms will not have access to all the industry-specific data needed to fine-tune those algorithms to particular application scenarios.

complementary capital and skills, such as academia and competitor firms, is crucial. In contrast, for technologies that are *not* general-purpose, this type of coordination is less significant and sometimes detrimental to a nation's competitive advantage, as the innovating firm could leak technical secrets.²⁷

Second, GPTs place demands on human capital. In describing the connection between skill formation and technological fitness, scholars often delineate between general skills and industry-specific skills. According to this perspective, skill formation institutions that optimize for the former are more conducive to technological domains characterized by radical innovation, while institutions that optimize for the latter are more favorable for domains marked by incremental innovation.²⁸ GPT diffusion entails both types of skill formation. The skills must be specific to a rapidly changing GPT domain but also broad enough to enable GPT adoption across many industries.²⁹ Strong linkages between R&D-intensive organizations at the technological frontier and application areas far from the frontier also play a key role in GPT diffusion. This draws attention to the interactions between researchers who produce innovations and technicians who help absorb them into specific contexts.³⁰

Education and training systems that foster relevant engineering skills for a GPT, or what I call *GPT skill infrastructure*, address both constraints. These institutions not only supply engineering talent but also standardize best practices associated with GPTs, thereby coordinating information flows between the GPT sector and application sectors. Indeed, the emergence of distinct engineering specialties, such as chemical engineering and electrical engineering, have proved essential in widening knowledge bases in the wake of a new GPT.³¹ Computer science, another engineering-oriented field, was central to U.S. leadership in the information revolution.³² While GPT diffusion is

³² Vona and Consoli. 2014.

dependent on many other factors, I limit my analysis to institutions of skill formation because their effects permeate across other institutional arrangements.³³

The institutional competencies for exploiting LS product cycles are different. Historical analysis informed by this frame highlights heroic inventors like James Watt and pioneering research labs at large companies.³⁴ Studying which countries benefited most from emerging technologies over the past two centuries, Herbert Kitschelt prioritizes the match between the properties of new technologies and sectoral governance structures. By way of illustration, under his framework, tightly coupled technological systems with high causal complexity, such as nuclear power systems and aerospace platforms, are more likely to flourish in countries that allow for extensive state support.³⁵ In other studies, the key institutional factors behind LS product cycles are education systems that subsidize scientific training and R&D facilities in new industries.³⁶ These approaches equate technological leadership with a state's success in capturing market shares and monopoly profits in new industries.

Competing interpretations of leadership in chemicals during the IR-2 crystallize these differences. Based on the LS template, the standard account accredits Germany's late-19th century dominance in the chemical industry — with control over 90 percent of global production of synthetic dyes — to its investments in scientific research and highly skilled chemists.³⁷ GPT diffusion spotlights other institutions that complemented the extension of chemical processes to a wide range of industries beyond synthetic dyes, such as food production, metals, and textiles. Under the GPT model, the U.S., not Germany, achieved leadership in chemicals because it first institutionalized the discipline of chemical engineering. Despite its disadvantages in synthetic dye

production and chemical research, the U.S. was more effective in broadening the base of chemical engineering talent and coordinating information flows between fundamental breakthroughs and industrial applications.³⁸

My theoretical framework differs from related work on the political economy of technological change.³⁹ Scholars attribute the international competitiveness of nations to broader institutional contexts, including democracy, national innovation systems, and property rights enforcement.⁴⁰ Since this paper is limited to the study of shifts in productivity leadership at the technological frontier, many of these factors, such as those related to basic infrastructure and property rights, will not explain differences among technologically advanced nations. Additionally, most of the institutional factors put forth to explain the productivity of nations are technology-agnostic, in that they treat all forms of technological change equally. In contrast, I am specific about GPTs as the sources of shifts in competitiveness at the technological frontier.

Other theories identify key technologies but leave institutional factors at a high level of abstraction. Some scholars posit that the lead economy's monopoly on leading-sector innovation eventually erodes because of "ubiquitous institutional rigidities."⁴¹ Unencumbered by vested interests that resist disruptive technologies, rising challengers inevitably overtake established powers. Because these explanations are underspecified, they cannot account for cases when established leaders sustain their advantage.⁴²

III. Assessing GPT Diffusion Across Industrial Revolutions

The differences between the GPT and LS explanations map onto diverging observable implications for how technological revolutions produce economic power transitions. First, I observe whether emerging technologies generate growth differentials among leading economies through GPT diffusion or LS product cycles. Under the GPT diffusion pathway, there should be an extended lag between initial breakthroughs and their ultimate impact on economic productivity. Additionally, dominating innovation in new industries is not essential for a state to effectively capitalize on a technological revolution; rather, it must lead in the diffusion of GPTs across the entire economy. By extension, that state's productivity growth should be dispersed across a broad range of industries, not concentrated in a few leading sectors.

Second, I assess whether institutional competencies can account for certain countries' success in exploiting GPT diffusion or LS product cycles. If GPT diffusion holds, the state that gains or sustains economic leadership should have an advantage over its rivals in GPT skill infrastructure. Examples include institutions that widen the repository of engineering skills linked to GPTs, standardize best practices associated with a GPT, and strengthen university-industry linkages in the GPT. Additional evidence of the GPT diffusion theory's explanatory power would be that other countries had advantages in the institutions that complement LS product cycles, such as scientific research infrastructure and sectoral governance structures.

I employ within-case congruence tests and process-tracing to evaluate the predictions of the two mechanisms against the empirical record.⁴³ The universe of cases most useful for assessing the GPT and LS mechanisms are technological revolutions (cause) that produced an economic power transition (outcome) in the industrial period. Following guidance on testing competing mechanisms that prioritize typical cases where the cause and outcome are clearly present, I investigate the first

⁴³ Blatter and Haverland 2012, 144; George and Andrew Bennett 2005, 181-204.

industrial revolution (IR-1) and second industrial revolution (IR-2).⁴⁴ Both cases featured periods of particularly disruptive advances, highlighted by many studies as “technological revolutions,”⁴⁵ and economic power transitions, when one great power sustains growth rates at substantially higher levels than its rivals.⁴⁶ I also study Japan’s challenge to American economic leadership in the third industrial revolution (IR-3), which ultimately failed. This deviant case can disconfirm mechanisms and help explain why they break down.⁴⁷

Given space constraints, what follows is a full analysis of the IR-2 case and abridged summaries of the IR-1 and IR-3 cases. The supplementary appendix provides extended discussions of those other cases and the research design.

SECOND INDUSTRIAL REVOLUTION

In the late nineteenth century, the technological and geopolitical landscape transformed in ways familiar to observers of today’s environment. “AI is the new electricity,” goes a common refrain that compares current advances in machine intelligence to electrical innovations from 150 years ago. Those fundamental breakthroughs, alongside others in steel, chemicals, and machine tools, sparked a “Second Industrial Revolution” (IR-2), which unfolded from 1870 to 1914.⁴⁸ According to some scholars, one would be hard-pressed to find another period with a higher density of important scientific advances.⁴⁹

By the end of the period, Britain’s decline and the rise of Germany and the U.S. yielded a new balance of economic power, which one historian describes as a “shift from monarchy to oligarchy, from a one-nation to a multi-nation industrial system.”⁵⁰ Indicators of per-capita

⁴⁴ Beach and Pedersen 2018; Goertz 2017.

⁴⁵ Gilpin 1975, 69. Related terms include “technology waves” (Milner and Solstad 2021) and “long waves” (Goldstein 1988).

⁴⁶ For related concepts, see Drezner 2001, 4; Modelski and Thompson 1996; Moe 2009; Reuveny and Thompson 2001.

⁴⁷ Beach and Pedersen 2018, 861-863; Goertz 2017, 66.

⁴⁹ Mowery and Rosenberg 1991, 22.

⁵⁰ Landes 1969, 247.

industrialization, per-capita GDP, and labor productivity all confirm that the U.S. overtook Britain in productivity leadership.⁵¹

The IR-2 case favors the LS mechanism in terms of background conditions and existing theoretical explanations, making it a most-likely case for the LS mechanism and a hard test for the GPT mechanism. In the 1880s, major technological innovations spurred the growth of electrical, chemical, and steel industries in Britain's rivals, which matches the general outlines of the LS explanation.⁵² Many international relations scholars hold up the IR-2 as a classic case of power transitions caused by LS product cycles.⁵³ According to this perspective, Germany surpassed Britain in the IR-2 because it was "the first to introduce the most important innovations" in key sectors such as electricity and chemicals.⁵⁴ Scholarship on today's rising powers follows a similar template, comparing China's scientific and technological capabilities to Germany's ability to develop major innovations in chemicals.⁵⁵

Historical evidence from the IR-2 challenges this conventional narrative. No country monopolized innovation in leading sectors such as chemicals, electricity, steel, and motor vehicles. Productivity growth in the U.S. was not dominated by a few R&D-based sectors. Moreover, some of the most prominent technological breakthroughs, including in electricity and chemicals, required a gradual, protracted process of diffusion across many sectors before their impact was felt. This made them unlikely key drivers of the U.S.'s rise before 1914.

Instead, the IR-2 case supports the GPT mechanism. Spurred by inventions in machine tools, the industrial production of interchangeable parts, known as the "American system of manufacturing," embodied the key GPT trajectory. The U.S. did not lead the world in producing the

⁵² Rostow 1978.

⁵³ Gilpin 1981; Gilpin 1987; Kennedy 2018, 51; Modelski and Thompson 1996.

⁵⁴ Akaev and Pantin 2014, 869.

⁵⁵ See, for example, Beckley 2011, 63-72.

most advanced machinery; rather, it had an advantage over Britain in adapting machine tools across almost all branches of industry. Though the American system's diffusion also required a long gestation period, the timing matches with America's industrial rise. Incubated by the growing specialization of machine tools in the 1830s and 1840s, the application of interchangeable parts across a broad range of manufacturing industries was the key driving force of America's relative economic growth in the IR-2.

Since a nation's success in adapting to technological revolutions is determined by how well its institutions complement the demands of emerging technologies, the GPT model of the IR-2 highlights institutional factors that differ from those featured in standard accounts. LS-based theories tend to emphasize Germany's institutional advantages in scientific education and industrial R&D. In contrast, the IR-2 case analysis points toward the U.S.'s edge in education and training systems that widened the skill base and standardized best practices in mechanical engineering. These institutional advantages enabled the U.S. to address engineering talent shortages and ineffective coordination between the GPT sector and application sectors — two key constraints on GPT diffusion.

GPT vs. LS Mechanism in the IR-2

Which technological changes could have sparked the economic power transition before World War I? The IR-2 was an age of dizzying technological breakthroughs, including but not limited to the electric dynamo (1871), the first internal combustion engine (1876), the Thomas process for steel manufacturing (1877), and the synthesis of indigo dye (1880). Tracking down how every single technical advance could have affected the growth differentials among Britain, Germany, and the U.S. is unmanageable, so I focus on technological changes that could have initiated LS and GPT trajectories. Confirmed to meet the established criteria for leading sectors or GPTs, these technological drivers serve as the fields of reference for assessing the validity of the GPT and LS

mechanisms in this case. Specifically, I study the chemicals, electrical equipment, automobile, and steel industries as candidate leading sectors, as well as chemicalization, electrification, and interchangeable manufacture as candidate GPTs.⁵⁶

GPT diffusion and LS product cycles present two competing interpretations regarding the IR-2's impact timeframe. In the 1870s and 1880s, new leading sectors emerged off the back of major breakthroughs in electricity, chemicals, and steel. According to the expected timeline of the LS mechanism, these new industries should have stimulated substantial growth in the early stages of their development, bringing about a pre-WWI upheaval in the industrial balance of power.⁵⁷ This leads to the first prediction:

P1.LS: The electrical equipment, chemical, automobiles, and/or steel industries made a significant impact on the U.S.'s rise to productivity leadership before 1914.

The GPT trajectory gives a different timeline for when the productivity benefits from major technological breakthroughs were realized on an economy-wide scale. Before stimulating economy-wide growth, the candidate GPTs that emerged in the 1880s — tied to advances in electricity and chemicals — required many decades of complementary innovations in application sectors and human capital upgrading. These candidate GPTs should have only contributed modestly to the U.S.'s industrial rise before World War I, with impacts, if any, materializing toward the very end of the period.

If the GPT mechanism was operational, the full impact of advances in machine tools should have taken effect during this period. By the start of the IR-2, mechanization spurred by advances in machine tools, including the turret lathe (1845) and universal milling machine (1861) was at a later stage of development than other candidate GPT trajectories.⁵⁸

⁵⁶ On justification for GPT and LS selection, including overlap between candidate GPTs and leading sectors, see supplementary appendix.

⁵⁷ Gilpin 1987, 98, 112; Modelski and Thompson 1996, 69; Moe 2007, 426; Thompson 1990, 226.

⁵⁸ Hobsbawm 1968, 147.

P1a.GPT: Electrification and chemicalization did not make a significant impact on the U.S.'s rise to productivity leadership before 1914.

P1b.GPT: The extension of interchangeable manufacture made a significant impact on the U.S.'s rise to productivity leadership before 1914.

Developments in chemicals and electricity provide evidence against the LS interpretation. In 1914, the U.S. was home to only seven dye-making firms.⁵⁹ Major U.S. chemicals firms did not establish industrial research laboratories like those of German counterparts until the first decade of the 20th century.⁶⁰ Thus, it is very unlikely that chemical innovations made a meaningful difference to growth differentials between the U.S. and Britain before 1914.

At first glance, the growth of the German chemical industry aligns with LS expectations. Germany was the first to incorporate scientific research into chemicals production, resulting in the synthesis of many artificial dyes before 1880.⁶¹ Overtaking Britain in leadership of the chemical industry, Germany produced 140,000 tons of dyestuffs in 1913, more than 85 percent of the world total.⁶²

While Germany's rapid growth trajectory in synthetic dyes was impressive, the greater economic impacts of chemical advances materialized *after* 1914 through a different pathway: "chemicalization," or the spread of chemical processes across ceramics, food-processing, glass, metallurgy, petroleum refining, and many other industries.⁶³ Prior to key chemical engineering advances in the 1920s, industrial chemistry was focused on making chemical products, such as synthetic dyes, with limited attention to unifying principles across the manufacture of different products. The rapid expansion of chemical-based industries in the 20th century owed more to these later improvements in chemical engineering than earlier progress in synthetic dyes.⁶⁴

Electrification's impact on U.S. productivity growth mirrored that of chemicalization. From 1880 to 1930, power production and distribution systems gradually evolved from systems driven by a central steam engine to electric unit drive, a system where electric motors powered individual machines. Unit drive did not become the predominant method until the 1920s.⁶⁵ Estimates of electric motors' share of horsepower in manufacturing as well as the causal effects of electrical patenting activity on per capita growth, along with other quantitative indicators, confirm that electrification's impact on U.S. economic productivity became significant only after 1914.⁶⁶

When assigning credit to certain technologies for major upheaval in global affairs, awe of the new often overwhelms respect for the old. Yet, careful tracing reveals the persevering impact of earlier developments in machine tools. During the IR-2, technical advances in machine tools were incremental, continuous improvements that helped disseminate transformative breakthroughs from the mid-19th century, such as the turret lathe and the universal milling machine.⁶⁷

Profiles of key application sectors and quantitative indicators validate the timeline expected by GPT diffusion theory. Profiles of key application sectors and quantitative indicators validate this expected timeline. Marking 1880 as when “the proliferation of new machine tools in American industry had begun to reach torrential proportions,” Rosenberg outlines how three application sectors — sewing machines, bicycles, and automobiles — successively adopted improved metal-cutting techniques from 1880 to 1910.⁶⁸ By 1914, the machine tool industry had grown to 409 firms with a total output of around \$31.5 million.⁶⁹ The number of potential machine tool users multiplied fifteen-fold from just 95,000 workers in 1850 to almost 1.5 million in 1910.⁷⁰ Patenting data

identifies the last third of the 19th century as when extensive technological convergence characterized the machine tool industry and application sectors.⁷¹

When spelling out how the IR-2 produced an economic power transition, the two mechanisms also stress different phases of technological change. According to the LS mechanism, Britain's industrial prominence waned because it lost its dominance of innovation in the new industries of the IR-2. The U.S. and Germany benefited from the monopoly profits linked to being lead innovators in electricity, chemicals, automobiles, and steel. For instance, many LS accounts attribute Germany's rise to its dominance of innovations in the chemical industry, "the first science-based industry."⁷²

GPT diffusion has different expectations regarding the key driver of growth differentials. Where innovations are adopted more effectively is more important than where they are first introduced. The GPT mechanism expects that Britain lost its industrial preeminence because the IR-2's candidate GPTs diffused more intensively in the U.S. and Germany. This sets up the following predictions:

P2.LS: German and American advantages in the production and exports of electrical equipment, chemicals, automobiles, and/or steel were crucial to their productivity leadership.

P2.GPT: American advantages in the diffusion of interchangeable manufacture were crucial to its productivity leadership.

Cross-country historical evidence on the 2IR's technological drivers illustrates that the U.S.'s true comparative advantages over other advanced economies were rooted in absorption and diffusion capabilities. In electricity, for example, innovation leadership was fiercely contested among the industrial powers. The U.S., Germany, Britain, and France all built their first central power stations, electric trams, and AC power systems within a span of nine years, but the U.S. clearly led in the diffusion of these systems: U.S. generating capacity in AC power more than doubled that of the

⁷¹ Thomson 2010, 26.

⁷² Moe 2007, 125. See also Drezner 2001, 11-18.

next closest competitor in 1912/1913.⁷³ Britain, despite introducing the steam turbine and other significant electrical innovations, lagged behind in adopting electrification at scale.⁷⁴

In chemicals, the success of both the U.S. and German chemical industries suggests that no one country monopolized innovation in this sector. Germany's synthetic dye industry excelled not because it generated the initial breakthroughs in aniline-violet dye processes — in fact, those were first pioneered in Britain — but because it had perfected these processes for profitable exploitation.⁷⁵ Similar dynamics characterized the U.S. chemical industry.⁷⁶

Moreover, the limited role of electrical and chemical exports in spurring American growth casts further doubt on the significance of monopolizing innovation. The British share of global chemical exports almost doubled the U.S. share in 1913.⁷⁷ Overall, the U.S. derived only eight percent of its national income from foreign trade in 1913, whereas the corresponding proportion for Britain was 26 percent.⁷⁸ Even though the U.S. led in electrification, Germany captured around half of the world's exports in electrical products.⁷⁹

If monopoly profits in any leading sector propelled the U.S. and Germany's industrial rise, it would have been the steel industry. Germany and the U.S. made remarkable gains in total steel output over this period, and scholars commonly employ crude steel production as a key indicator of British decline and the shifting balance of industrial power in the decades before World War I.⁸⁰ Nonetheless, Britain pioneered major innovations in steelmaking and maintained a revealed comparative advantage in iron and steel industries.⁸¹

⁸¹ Hobsbawm 1968, 159; Yearly Index of Forging and Heat Treating 1922, 357.

How to square this with Germany's dominance in total steel output? In truth, new steelmaking processes created two separate steel industries. Shifting toward a type of steel that was higher in quality and price, Britain produced about four times more open-hearth steel than Germany in 1890.⁸² Germany produced cheap Thomas steel and exported a large amount at dumping prices. Some of Germany's steel exports went to Britain, where they were processed into higher-quality steel and re-exported. This evidence exposes what one scholar calls "the myth of the technological superiority and outstanding productivity of the German steel industry before and after the First World War."⁸³

In line with the implications of GPT diffusion, comparative estimates confirm a substantial U.S. lead in mechanization in the early 20th century. In 1907, machine intensity in the U.S. was more than two times higher than rates in Britain and Germany.⁸⁴ In 1930, the earliest year for which data on installed machine tools per employee is available, Germany trailed the U.S. in this metric by 10 percent, with an even wider gap in the tools most crucial for mass production.⁸⁵

This disparity in mechanization was not rooted in the U.S.'s exclusive access to special innovations in machine tools. In terms of quality, British machine tools were superior to their American counterparts throughout the IR-2 period, German firms also had advantages in certain fields like sophisticated power technology.⁸⁶ Rather, the distinguishing feature of the U.S. machine tool industry was excellence in adapting innovations across industries.⁸⁷ Reports by British study trips to the U.S. provide some of most detailed, reliable accounts of transatlantic differences in mechanization. British inspection teams reported that America's competitive edge came from the

“adaptation of special apparatus to a single operation in almost all branches of industry”⁸⁸ and “eagerness with which [the Americans] call in the aid of machinery in almost every department of industry.”⁸⁹ When evaluating the significance of certain technological innovations to economic leadership in this period, economic historians also elevate machine tools and the American system above chemical and electrical innovations.⁹⁰

Finally, regarding the breadth of growth, the third dimension on which the two mechanisms diverge, the LS trajectory expects that a narrow set of new industries accounted for productivity differentials, whereas the GPT trajectory holds that a broad range of industries contributed to productivity differentials. Since the pattern of U.S. economic growth is most relevant because it overtook Britain as the economic leader, these differences produce the following predictions:

P3.LS: Productivity growth in the U.S. was concentrated in the electrical equipment, chemical, automobile, and/or steel industries.

P3.GPT: Productivity growth was spread across a broad range of industries linked to interchangeable manufacture.

Historical data support the GPT model’s predictions of pervasive U.S. productivity growth. Kendrick’s detailed study of U.S. productivity growth in this period depicts a relatively balanced distribution. Among the industries studied, nearly 60 percent averaged between one to three percent increases in output per labor-hour from 1899 to 1909.⁹¹ Per updates to Kendrick’s estimates, “great inventions,” roughly corresponding to the candidate leading sectors, accounted for only 29 percent of American total factor productivity (TFP) growth from 1899-1909.⁹² From 1899 to 1941, 33 of 38 sectors averaged at least 1 percent annual TFP growth.⁹³ Despite employing 40 percent of all

⁹³ Bakker et al. 2019, 2288

research scientists in 1920, the chemical industry was responsible for only 7 percent of U.S. TFP growth throughout the following decade.⁹⁴

Broad-based productivity growth in the U.S. economy does not necessarily mean that a GPT was at work. Macroeconomic factors or the accumulation of various, unconnected sources of TFP growth could produce this outcome. Therefore, if the GPT trajectory captures the breadth of growth in the IR-2, then the historical evidence should connect broadly distributed productivity growth in the U.S. to developments in machine tools.

Although spillovers from interchangeable manufacturing were not boundless, the extension of the American system boosted productivity in a wide range of sectors. Applications of this system of special tools reshaped the processes of making firearms, furniture, sewing machines, bicycles, automobiles, cigarettes, clocks, boots and shoes, scientific instruments, typewriters, agricultural implements, locomotives, and naval ordnance.⁹⁵ Its influence covered “almost every branch of industry where articles have to be repeated.”⁹⁶ Per a 1930 inventory of American machine tools, the earliest complete survey, nearly 1.4 million metalworking machines were used across 20 industrial sectors.⁹⁷ Progress in “certain types of new products developed by the machinery and other producer industries (that) have broad applications across industry lines” were a key source of the “broad, pervasive forces that promote efficiency throughout the economy.”⁹⁸

Institutional Complementarities: GPT skill infrastructure in the IR-2

Which institutions for skill formation were most central to the U.S.’s ability to take advantage of new advances in machine tools? Previous studies of economic rivalry among great powers in the IR-2 attribute Germany’s technological success in this period to its investments in

R&D facilities and advanced scientific and technical education.⁹⁹ American leadership in adoption of interchangeable manufacturing methods was beholden to a different set of institutions for skill formation. Progress in this domain did not depend on new scientific frontiers and industrial research laboratories.¹⁰⁰ Widespread mechanization in the U.S. rested, instead, on a broad base of mechanical engineering skills.

With the development of more automatic and precise machine tools throughout the 19th century, mechanization demanded more of machinists and mechanical engineers. Before 1870, U.S. firms relied on informal apprenticeships at small workshops for training machine tool designers and users, as engineering education at traditional colleges did not prioritize mechanical engineers.¹⁰¹ Yet, craft-era methods and skills were no longer sufficient to handle the enhanced sophistication of machine tools.¹⁰² Thus, in the mid-18th century, the need for more formal technical instruction in mechanical engineering presented a strong constraint on the U.S.'s potential for mechanization.

Over the next few decades, advancements on three main fronts met this need for a wider pool of mechanical engineering expertise. First, in 1862, the U.S. Congress passed the Morrill Act, financing the creation of land-grant colleges dedicated to the agricultural and mechanical arts. With support from the land-grant funds, the number of U.S. engineering schools multiplied from six in 1862, when the Morrill Act was passed, to 126 in 1917.¹⁰³ These schools were especially significant in widening the base of professional mechanical engineers. In 1900, out of all students pursuing mechanical engineering at U.S. higher education institutions, 88 percent were enrolled in land-grant colleges.¹⁰⁴

¹⁰³ Noble 1977, 24; see also Maloney and Caicedo 2017, 12-13.

¹⁰⁴ Dalby 1903, 39.

Second, new technical institutes also served demands for mechanical engineering training. Pure technical schools like the Worcester Polytechnic Institute, founded in 1868, and the Stevens Institute of Technology, founded in 1870, developed mechanical engineering curricula that would become templates for engineering programs at universities and colleges.¹⁰⁵ Embedded with local and regional businesses, technical institutes developed laboratory exercises that would familiarize students with real-world techniques and equipment. In this respect, these institutes and land-grant colleges “shared a common belief in the need to deliver a practice-oriented technical education.”¹⁰⁶

Another significant development in the spread of mechanical engineering knowledge was the emergence of professional engineering societies that created industrial standards. Standardization in various machine processes and components, such as screw threads, helped spread mechanization across disparate markets and communities.¹⁰⁷ The American Society of Mechanical Engineers and other similar associations coordinated to share best practices and improve knowledge flows between the machine tool industry and application sectors.¹⁰⁸

Both Britain and Germany fell short of the U.S. standard in GPT skill infrastructure. For Britain, the key gap was in the supply of mechanical engineering talent. In 1901, there were probably around 2600 students enrolled in full-time higher technical education in the UK.¹⁰⁹ If this population was limited to those in their third or fourth year of full-time study – an important condition because many UK programs, unlike German and American institutions, did not progress beyond two years of study – that leaves only about 400 students.¹¹⁰ By comparison, in mechanical engineering programs *alone*, the U.S. had 4,459 students enrolled in higher technical education in 1900.¹¹¹

¹¹⁰ Wertheimer 1903; Wickenden 1930, 36.

¹¹¹ Dalby 1903, 39..

Controlling for population differences, the U.S. substantially outpaced Britain in engineering density, as measured by the number of university-educated engineers per 100,000 male laborers.¹¹²

Germany developed a more practical and accessible form of higher technical education than Britain. From 1870 to 1900, enrollments in German technical colleges increased nearly fourfold from 13,674 students to 32,834 students.¹¹³ Its struggles were with weak linkages between mechanical engineering education and industrial applications. Key German standards bodies and technical colleges prioritized scientific and theoretical education at the expense of practical skills — a trend “most pronounced in mechanical engineering.”¹¹⁴ Articles in the *Zeitschrift des Vereines Deutscher Ingenieure* (Journal of the Association of German Engineers) lamented that German institutions were not equipping students with practical skills and the ability to manage factories and workshops. Compared to their German peers, American students spent less time with theoretical schooling and far more time with exercises in mechanical technical laboratories and other types of practical training.¹¹⁵

Crucially, and contrary to the LS model’s expectations, the U.S.’s institutional adaptations to new opportunities presented by interchangeable manufacture were not rooted in cultivating scientific experts. The best and brightest American researchers furthered their education at European universities. Even proponents of American engineering education concluded that “strictly scientific and intellectual education in American technological schools” did not even match “the average of a secondary industrial school” in Germany.¹¹⁶ According to one study of the National Association of German-American Technologists, an organization that regularly facilitated technical

exchanges between the two countries, Germany technical institutes held an edge over their U.S. peers in terms of research on mechanical engineering techniques.¹¹⁷

FIRST INDUSTRIAL REVOLUTION

Few historical events have shaken the world like the IR-1 (1780-1840). Among the manifold contours and consequences of the IR-1, two phenomena stand out for my purposes. The first is the remarkable technological progress that inaugurated the IR-1 period. Everything was changing in part because so many *things* were changing — water frames, steam engines, puddling processes not least among them. The second is Britain’s rise to unrivaled hegemony. Britain became the world’s most advanced industrial power by the mid-19th century. Crucially, Britain’s economic dominance was not based on the overall size of its economy — China was the world’s largest economy during this period — but on its ability to take advantage of the technologies of the industrial revolution to become “the world’s most advanced productive power.”¹¹⁸ Starting in the 1820s, Britain sustained productivity growth at levels substantially higher than France and the Netherlands.¹¹⁹

No study of technological change and power transitions is complete without an account of the IR-1. For both the LS and GPT mechanisms, the IR-1 functions as a typical case that is held up as paradigmatic of technology-driven power transitions. In existing international relations scholarship, the standard account attributes Britain’s industrial ascent to its dominance of innovation in the IR-1’s leading sectors, most notably the cotton textiles industry. Present-day scholarship and policy discussions often draw upon a LS model of the IR-1, analogizing developments in information technology and biotechnology to the effects of steam power and cotton textiles in the industrial revolution.

¹¹⁷ Braun 1983, 16. While my priority is on demonstrating the explanatory power of GPT diffusion theory relative to the LS account, the supplementary appendix assesses alternative factors in the IR-2 case.

¹¹⁸ Kennedy 2018, 53.

¹¹⁹ Bairoch 1982, 322; Bolt and van Zanden 2020, 9; Crafts 1995, 752.

The historical evidence challenges many of these assumptions. Time-series data on output growth of 26 industries helps differentiate the growth schedules of the cotton textiles and iron industries. Expanded uses of iron in machine-making — a gradual process compared to the growth of cotton textiles — matched the timeline of when British industrialization outpaced its rivals. In contrast, Britain's cotton textile industry grew exceptionally fast following major technological innovations in the 1760s but experienced a deceleration in output growth from the 1780s onward. Based on this early peak, it is unlikely that the cotton industry was the main driver of the post-1815 upsurge in British productivity growth.¹²⁰

The IR-1 case also demonstrates that Britain's advantage in adopting iron machinery across many sectors, as opposed to monopoly profits from innovations in cotton textiles, was crucial to its industrial ascendancy.¹²¹ While the iron industry accounted for a much smaller proportion of Britain's exports and national income, its impact on productivity materialized through the diffusion of iron machinery across a wide range of sectors.¹²² British industrialization drew from widespread technological advances connected to access to cheap iron and mechanization.¹²³ Overall, the GPT trajectory fits the IR-1 case better than the LS trajectory.

Since no country monopolized innovations in metalworking processes and Britain's competitors could also absorb innovations from abroad, why did Britain gain the most from this GPT trajectory? In all countries, as technical advances surged, institutional adjustments raced to cultivate the skills required to keep pace. As expected by GPT diffusion theory, Britain benefited from a superior system for disseminating GPT-related knowledge, especially its institutional advantages in widening the talent base of mechanically-skilled engineers. In contrast to the common

¹²⁰ Greasley and Oxley 2000, 114. Farnie 2003, 734. Previous accounts also conflated the significance of some advances with their rapid diffusion. The steam engine, for example, only made limited contributions to Britain's rise to industrial prominence in this period due to its delayed diffusion. von Tunzelmann 1978.

¹²³ Horrell et al. 1994, 557; Nuvolari 2009, 223; Sullivan 1990, 354.

refrain that Britain's leadership was rooted in the genius of individual innovators like James Watt, the historical data shows that Britain owed its success to the “tweakers” and “implementers” who facilitated mechanization across many industries.¹²⁴ In fact, France and other industrial rivals were far ahead in the institutions of higher technical education that trained expert scientists and engineers.¹²⁵ However, they lagged behind Britain with respect to a system that connected top engineers to a wider base of talent needed to diffuse the iron-based GPT.¹²⁶

THIRD INDUSTRIAL REVOLUTION

In the two previous cases, an industrial revolution preceded a shift in global leadership. Britain established its economic dominance in the early 19th century, and the U.S. took the mantle in the late 19th century. During the last third of the 20th century (1960-2000), many recognized that the technological environment was undergoing a transformation akin to those of the first and second industrial revolutions. A cluster of information technologies, connected to fundamental breakthroughs in computers and semiconductors, disrupted the foundations of many industries. The term “Third Industrial Revolution” (IR-3) came to refer to an epochal shift from industrial systems to information-based and computerized systems.¹²⁷ Amidst this upheaval, many thought Japan would follow in the footsteps of Britain and the U.S. to become the “Number One” industrial power.¹²⁸

Of the countries racing to take advantage of the IR-3, Japan's remarkable advances in electronics and information technology garnered a disproportionate share of the spotlight. “[T]he more advanced economies, with Japan taking the lead in one industry after another, [were] restructuring their economies around the computer and other high tech industries of the third

¹²⁸ Vogel 1979.

industrial revolution,” Gilpin writes.¹²⁹ In the late 1980s and early 1990s, a torrent of works bemoaned the loss of U.S. technological leadership to Japan.¹³⁰ “Japan has...become the undisputed world economic champion,” declared Clyde V. Prestowitz, Jr, a former U.S. trade negotiator, in his best-selling book on U.S.-Japan relations.¹³¹

Past precedents loomed over these worries. Paul Kennedy and other historically minded thinkers likened the U.S. position in the 1980s to Britain’s backwardness a century earlier: two industrial hegemonies on the brink of losing their supremacy.¹³² Often alluding to the LS mechanism, these comparisons highlighted Japan’s lead in technologically progressive industries, such as consumer electronics or semiconductors. As Mowery and Rosenberg wrote in 1991, “Rapidly growing German domination of dyestuffs helped to propel that country into the position of the strongest continental industrial power. The parallels to the Japanese strategy in electronics in recent decades are striking.”¹³³ Many voices called for the U.S. to mimic features of Japan’s innovation system, such as the *keiretsu* system of industrial organization and the activist role of the Ministry of International Trade and Industry, which were viewed as critical to its strength in leading sectors.¹³⁴

However, the predicted economic power transition never occurred. To be sure, Japanese firms did take dominant positions in key segments of high-growth industries like semiconductors and consumer electronics. Additionally, Japan’s economy did grow at a remarkable pace, averaging an annual 2.4 percent increase in TFP between 1983 and 1991. However, Japan’s TFP growth stalled in the 1990s at an average of .2 percent per year — a period known as its “lost decade.” By 2002, the per capita GDP gap between Japan and the U.S. was larger than it had been in 1980.¹³⁵ Becoming

the world's leading producer in high-tech industries, fulfilling the conditions posited by the LS mechanism, did not catalyze Japan's overtaking of the U.S. as the lead economy. This makes the IR-3 case evidence particularly damaging for the LS theory.

On the other hand, the case evidence shows that Japan did not lead the U.S. in the diffusion of general-purpose information and communications technology (ICT), which means the conditions for an economic power transition under the GPT mechanism were absent. During this period, Japan's TFP growth in ICT-*producing* sectors was similar to the U.S.'s trajectory; however, in sectors that intensively *used* IT, Japan's TFP growth lagged far behind that of its rival.¹³⁶ In particular, U.S. ICT-using service industries adapted better to computerization. In terms of labor productivity growth in these industries, the U.S. experienced the strongest improvement out of all OECD countries from the first half of the 1990s to the second half of the decade.¹³⁷ Conversely, Japan posted a decline on this metric.¹³⁸

The IR-3 case shows that the LS mechanism expects an outcome that does not occur — a U.S.-Japan economic power transition — because it fails to account for the U.S.'s relative success in GPT diffusion. As supported by a bevy of evidence, this advantage stemmed from the U.S.'s superior ability to cultivate the computer engineering talent necessary to advance computerization. According to one estimate, the U.S. ICT talent pool was increasing by nearly three times as much as Japan's per year.¹³⁹ Closer university-industry linkages in the U.S. system of higher education, compared to arrangements in Japan or Europe, provided a “thicker basis” for skill adjustments to computerization.¹⁴⁰ In this respect, evidence from this deviant case points toward GPT diffusion as the preferred explanation.

IV. Conclusion

This article has presented a novel theory of how and when technological revolutions affect economic power transitions. My findings fill significant gaps in existing scholarship on how technological change affects the global balance of power, with broader implications for studying the effects of technological change on international politics. Scholars recognize that technological revolutions can disrupt the economic balance of power, but few have systematically investigated how this process occurs. GPT diffusion theory suggests modifications to the standard explanation based on leading sectors.¹⁴¹ Since shifts in economic leadership often precede disruptions to the military balance of power and hegemonic conflict, this paper contributes to questions power transition scholars have long grappled with related to when and why hegemons come and go.¹⁴²

Additionally, GPT diffusion theory challenges the conventional wisdom about how AI and other revolutionary technologies could shape the current U.S.-China power balance. Drawing on the LS template, policymakers and scholars emphasize China's challenge to U.S. technological leadership by citing indicators of China's capacity to generate new breakthroughs in AI. GPT diffusion theory suggests that the key technological trajectory is the relative success of the U.S. and China in adopting AI advances across many industries in a gradual process that will play out over multiple decades. The most important institutional factors, therefore, may not be R&D support for elite labs and universities or government capacity to support national champions but rather those that widen the skill base in AI and enmesh AI engineers in cross-cutting networks with entrepreneurs and scientists. Based on intensive adoption margins for related ICTs like cloud computing, academic-

¹⁴¹ Drezner 2019, 289; Kennedy 2018; Tellis et al. 2000.

¹⁴² Reuveny and Thompson 2001; Wohlforth 1999, 32.

corporate linkages in AI, and measures of engineering-oriented AI education, the U.S. is better positioned than China to implement AI at scale.¹⁴³

It is necessary to acknowledge limitations in translating lessons from past industrial revolutions and power transitions to the present. Scholars have argued that the current era of U.S.-China competition differs from previous eras with respect to the size of the technological and military gap as well as the greater difficulty of translating economic capacity into military capabilities.¹⁴⁴ Future research should probe factors such as the globalization of innovation, qualities unique to digital technologies, and changes in the overall pace of technological change. Still, the historical cases covered in this article exert substantial influence in the minds of academics and policymakers. At the very least, this article submits different lessons to be learned from these guiding precedents.

¹⁴³ The supplementary appendix includes an extended application of GPT diffusion theory to U.S.-China technological competition.
